IMPLICATIONS FOR THE ORIGIN OF GRB 070201 FROM LIGO OBSERVATIONS
LIGO-P070081-04-Z FOR INTERNAL DISTRIBUTION ONLY - APJ TARGET

THE LSC
(Dated: RCS ; compiled 15 October 2007)

Draft version 15 October 2007

ABSTRACT

We analyzed the available LIGO data coincident with GRB 070201, a short hard γ-ray burst whose electromagnetically determined sky position is coincident with the spiral arms of the Andromeda galaxy (M31). Compact binary mergers of a neutron star and a black hole or a neutron star and soft γ-ray repeaters (SGRs) have been suggested as possible progenitors; both are possible sources of gravitational radiation. No plausible gravitational wave candidates were found within a 180 s long window around the time of GRB 070201. This result implies that a compact binary progenitor of GRB 070201, with masses in the range 1 $M_\odot < m_1 < 3 M_\odot$ and $1 M_\odot < m_2 < 40 M_\odot$, located in M31 is excluded at > 99% confidence. Indeed, if GRB 070201 were caused by a binary neutron star merger, we find that $D < 3.5$ Mpc is excluded, assuming random inclination, at 90% confidence. The result also implies that an unmodeled gravitational wave burst from GRB 070201 most probably emitted less than $4.4 \times 10^{50} M_\odot c^2$ $(7.9 \times 10^{50} \text{ ergs})$ in any 100 ms long period within the signal region if the source was in M31 and radiated isotropically at the same frequency as LIGO’s peak sensitivity (f ≈ 150 Hz). This upper limit does not exclude current models of SGRs at the M31 distance.

Subject headings: gamma-ray bursts – gravitational waves – compact object mergers – soft gamma-ray repeaters

1. INTRODUCTION

Gamma-ray bursts (GRBs) are intense flashes of γ-rays which are observed to be isotropically distributed over the sky (see, e.g.: Piran 2005; Meszaros 2002; references therein). The variability of the bursts on short time scales indicates that the sources are very compact. Combined observations, using γ-ray and x-ray satellites such as Vela, CGRO, BeppoSax, Swift, Konus-Wind, and INTEGRAL (see Klebesadel et al. 1973; Meegan et al. 1992; Paciesas et al. 1999; Frontera et al. 2000; Mazets and Golenetskii 1981; Gehrels et al. 2004, and references therein), with follow-up by optical and radio telescopes of the region around GRBs, have yielded direct observations of some afterglows. In turn, host galaxies were identified for some GRBs and their redshifts measured. The redshifts indicated that GRBs are of extra-galactic origin. Two types of GRBs are distinguished by their characteristic duration (see Kouveliotou et al. 1993; Gehrels et al. 2006) and are understood to have different origins.

Long GRBs have duration $\gtrsim 2$ s. Detailed observations of long GRBs demonstrate their association with star-forming galaxies ranging up to a redshift of $z \simeq 6.3$ (see Watson et al. 2006; Jakobsson et al. 2006, and references therein). Furthermore, several nearby long GRBs have been spatially and temporally coincident with supernovae (e.g. Campana et al. 2006; Hjorth et al. 2003; Galama et al. 1998).

Short GRBs have duration $\lesssim 2$ s. The progenitors of short GRBs are not so well understood. While there are associations with distant galaxies of many different types and different star formation histories, there is at least one powerful burst of γ-rays from a known Galactic source, SGR1806-20 (Nakar et al. 2006; Hurley et al. 2005). An attempt to associate all short GRBs with soft γ-ray repeaters (SGRs) suggested that at most 15% of them can be accounted for in this way (Nakar et al. 2006). Moreover, the spectral characteristics and energetics of other observed short GRB events and their follow-up afterglows seem to contradict this hypothesis in most cases (Nakar et al. 2006). The current leading hypothesis to explain most short GRBs is the merger of neutron star or neutron star + black hole binaries (see for example Nakar 2007, and references therein). However, to date no observations have definitively confirmed the association between short GRBs and binary mergers.

Therefore, given the candidate sources, it is plausible that GRB central engines are also strong gravitational wave (GW) emitters at frequencies accessible to ground-based detectors like LIGO, GEO-600, and Virgo (Abbott et al. 2005a; Acernese et al. 2006; Kocianek and Piran 1993; Abbott et al. 2006a, 2005b; Finn et al. 2004). Bursts of gravitational waves are expected to be emitted during the GRB event, with a characteristic duration comparable to that of the associated GRB, though the amplitude and frequency spectrum of the gravitational-wave burst are unknown. In the case of short GRBs produced by compact binary mergers, gravitational waves with relatively well-modeled amplitude and frequency evolution will be emitted during the inspiral phase of the binary system, preceding the event that produces the GRB.

GRB 070201 was an intense, short, hard GRB detected by Konus-Wind and INTEGRAL (SPI-ACS); it was also observed by Swift (BAT) but with a high-intensity background as the satellite was entering the South Atlantic Anomaly (Golenetskii et al. 2007a). The burst light-curve exhibited a multi-peaked pulse with duration $\sim 0.15$ s, followed by a much weaker, softer pulse that lasted $\sim 0.08$ s. Using early reports, Perley and Bloom (Perley and Bloom 2007) pointed out that the location annulus of the event intersected the outer spiral arms of the Andromeda galaxy (M31). A modified error box, centered $\approx 1.1$ degrees from the center of M31, was later reported (Pal’shin 2007; Hurley et al. 2007). The error box was later refined, however, it still over-
inspiral waves, peaks at a signal to noise ratio of 8 (see, e.g. Abbott et al. 2005b, and references therein). At the time of GRB 070201, this distance was 35.7 Mpc and 15.3 Mpc for the Hanford 4 km and 2 km detectors, respectively. However, the sensitivity of a detector to a gravitational wave depends on the location of the source on the sky and on the polarization angle of the waves. In the case of compact binaries, it also depends on the inclination angle of the orbital plane relative to the line of sight. At the time of GRB 070201, the binary inspiral reach in the direction of M31 was only about 43% of this maximum. More details of the instrumental sensitivity can be found in Sec. 2.

The search for gravitational waves from a compact binary inspiral focused on objects with masses in the ranges $1 M_{\odot} \leq m_1 \leq 3 M_{\odot}$ and $1 M_{\odot} \leq m_2 \leq 40 M_{\odot}$. The core of the search is matched filtering, cross-correlating the data with the expected gravitational waveform for binary inspiral and uses methods reported previously (see, e.g Abbott et al. 2005b, and references therein). Uncertainties in the expected waveforms can lead to decreased sensitivity of the search to the gravitational wave signal from the inspiral phase; this is particularly true of systems with higher masses and systems with substantial spin (Grandclement et al. 2003). This is accounted for by studying the dependence of sensitivity of the search to a variety of model waveforms based on different approximation methods.

The search for more generic transient gravitational waves coincident with the $\gamma$-ray burst is based on cross-correlating data from two detectors and does not make use of a specific model for the gravitational wave signal. This is an appropriate method when the gravitational wave signal is not well modeled theoretically, such as signals from the actual merger phase of a compact binary system or the core collapse phase of a supernova event.

The remainder of the paper is organized as follows. In Sec. 2, we discuss the LIGO detectors and the data taken around the time of GRB 070201. In Sec. 3, we report on the inspiral gravitational wave search, briefly reviewing the methods and algorithms used, and concluding with the astrophysical implications of the search for the GRB 070201 event. In Sec. 4, we report on the search for burst-like gravitational wave signals and present the astrophysical implications of that search. Since no plausible gravitational wave signal was detected above the background either in the inspiral or the burst search, we present the astrophysical implications of these results on the understanding of short GRBs in Sec. 5.

2. LIGO OBSERVATIONS

LIGO is comprised of three instruments at two geographically distinct locations (a 4 km detector and a 2 km detector at Hanford Observatory, referred to as H1 and H2, and a 4 km detector at Livingston Observatory, referred to as L1). Five science runs have been carried out to date. GRB 070201 occurred during the most recent science run, called S5, which started on November 4th, 2005 and ended on October 1st, 2007. All three LIGO detectors were operating at their design sensitivity (LSC 2007) throughout the S5 run.

The LIGO detectors use suspended mirrors at the ends of kilometer-scale, orthogonal arms to form a power-recycled Michelson interferometer with Fabry-Perot arms. A gravitational wave induces a time-dependent strain $h(t)$ on the detector. While acquiring scientific data, feedback to the mirror positions and to the laser frequency keeps the optical cavities near resonance, so that interference in the light from the
two arms recombining at the beam splitter depends on the difference between the lengths of the two arms. A photodiode senses the light, and a digitized signal is recorded at a sampling rate of 16384 Hz. The data are calibrated and converted into a strain time series.

The LIGO detectors have a sensitive frequency band extending from ~40 Hz to ~2000 Hz, with the maximum sensitivity at ≈150 Hz, which is limited at low frequencies by seismic noise and at high frequencies by laser shot noise. In addition, environmental disturbances, control systems noise, and other well understood noise sources result in a non-stationary and non-Gaussian background.

2.1. LIGO observations coincident with GRB 070201

At the time of the GRB trigger, both LIGO Hanford detectors were stable and recording scientific data quality. These detectors had been in science mode for more than 14 hours before the GRB trigger, and stayed in science mode for more than 8 hours after the GRB trigger, providing ample data for background studies.

An asymmetric 180 s on-source segment, −120/+60 s about the GRB trigger time, was searched for gravitational-wave signals. This choice (Abbott et al. 2005a, 2007a) is conservative enough to accommodate inspiral type signals, trigger time ambiguities, and theoretical uncertainties. We also implicitly assume that the propagation speed of the gravitational waves is the speed of light. The significance of candidate events was evaluated using studies covering several hours of off-source data from the same science mode stretch outside of, but near to, the on-source segment.

The ideal response of a detector to an incident gravitational wave is a weighted combination of the two underlying gravitational wave polarizations denoted by $h_x(t)$ and $h_y(t)$:

$$h(t) = F_\phi(t, \phi, \psi) h_x(t) + F_\psi(t, \phi, \psi) h_y(t).$$

The dimensionless weighting amplitudes, or antenna factors, $F_\phi$ and $F_\psi$, depend on the position $(\theta, \phi)$ of the source relative to the detector and the gravitational wave polarization angle $\psi$. For the location of GRB 070201, the root-mean-square (RMS) antenna factor, $F_{RMS}$, for both colocated and coaligned Hanford detectors was

$$F_{RMS} = \sqrt{F_\phi^2 + F_\psi^2}/2 = 0.304,$$

a combination which does not depend on the polarization angle $\psi$. Despite the sub-optimal location of GRB 070201 for the LIGO Hanford detectors, they still had significant sensitivity for the polarization state compatible with the detector.

2.2. Data quality for the times surrounding the GRB 070201 trigger

A suite of data quality tests were applied to LIGO data. No anomalous behavior was found in either instrument at the time of GRB 070201. On the other hand, a number of data quality issues were identified in the off-source time used for background estimation (which amounted to 60084 s, or 16.7 hr). Triggers were excluded from 530 s of coincident, off-source data so identified, or 0.9% of the off-source time.

Overflows in digital signals used in the feedback control systems were responsible for 29 s in H1 and 29 s in H2 of excluded time. Seismic noise in the 3–10 Hz band known to produce false alarms in H1 was used to veto 160 s of data. Disturbances that produced a loss in power in the H2 detector arm cavities larger than 4% were also vetoed, amounting to 163 s, which include 11 s when there were overflows in H2. No such fluctuations in arm power were observed in H1.

Additionally, in the search for a compact binary progenitor, there were losses in off-source live-time due to quantization on 180 s intervals. Each of these intervals was intended to be a trial treated the same as the central, on-source interval, for use in background determination.

For the burst analysis, three hours of data was used for the purpose of background estimation. The same data quality flags were considered as were used in the inspiral search but, due to the shorter length of the background used, only one data quality flag (an overflow in the H2 signal) was applied vetoing one of the 180-second segments in the three-hour background period.

Finally, 160 s of the off-source time contained simulated signals, injected intentionally at predetermined times to validate the detector response and signal detection algorithms, and therefore excluded from this data analysis.

3. SEARCH FOR GRAVITATIONAL WAVES FROM A COMPACT BINARY PROGENITOR

A number of searches for gravitational waves from compact binaries have been completed on the LIGO data (Abbott et al. 2005c, 2006b, 2005d, 2007b). Similar search methods were applied to the on-source time around GRB 070201 (Abbott et al. 2007c). In this section we briefly describe those methods, report the results of the search, and discuss their interpretation.

3.1. Search Method

The core of the inspiral search involves correlating the LIGO data against the theoretical waveforms expected from compact binary coalescence, i.e., matched filtering the data (Wainstein and Zubakov 1962). The gravitational waves from the inspiral phase, when the binary orbit tightens under gravitational-wave emission prior to merger, are accurately modeled in the band of LIGO sensitivity for a wide range of binary masses (Blanchet et al. 1995; Blanchet and Faye 2001). The expected gravitational-wave signal, as measured by LIGO, depends on the masses and spins of the binary elements, as well as the spatial location, inclination and orientation of the orbital axis. In general, the power of matched filtering depends most sensitively on accurately tracking the phase evolution of the signal. The phasing of compact binary inspiral signals depends on the masses and spins, the time of merger, and an overall phase. In a search for gravitational waves from compact binaries, one therefore uses a discrete set of template waveforms against which the data are correlated.

In this search, we adopt template waveforms which span a two-dimensional parameter space (one for each component mass) such that the maximum loss in signal-to-noise (SNR) for a binary with negligible spins would be 3%. While the spin is ignored in the template waveforms, we show below that the search is still sensitive to binaries with most physically reasonable spin orientations and magnitudes with only moderate loss in sensitivity. To generate a GRB, at least one of the objects in a compact binary must be a material object, probably a neutron star, while the second object must either be a neutron star or a stellar mass black hole with low enough mass (Vallisneri 2000; Rantsiou et al. 2007) to cause disruption of the neutron star before it is swallowed by the hole. The mass-parameter space covered by the templates is therefore $1 \, M_\odot < m_1 < 3 \, M_\odot$ and $1 \, M_\odot < m_2 < 40 \, M_\odot$. The number of template waveforms required to achieve this cov-
average depends on the detector noise curve; at the time of the GRB, 7171 and 5417 templates were required in H1 and H2, respectively.

The data from each of the LIGO instruments are filtered through the bank of templates. If the matched filter signal-to-noise exceeds a threshold $\rho^*$, the template masses and the time of the maximum signal-to-noise are recorded. For a given template, threshold crossings are clustered using a sliding window equal to the duration of the template as explained in (Allen et al. 2005). For each trigger identified in this way, the coalescence phase and the effective distance—the distance at which an optimally oriented and located binary would give the observed signal-to-noise assuming masses to be those of the template—are also computed. Triggers identified in each instrument are further required to be coincident in the time and mass parameters between the two operating instruments taking into account the correlations between those parameters. This significantly reduces the number of background triggers that arise from matched filtering in each instrument independently. Because H1 was more sensitive than H2, two different thresholds were used in the matched filtering step: $\rho^* = 5.5$ in H1 and $\rho^* = 4.0$ in H2. This choice takes advantage of the better sensitivity in H1 while still using H2 to reduce the rate of accidents.

To further reduce the background, two signal-based tests are applied to the data. First, a $\chi^2$ statistic (Allen 2005), which measures the quality of the match between the data and the template, is computed; triggers with large $\chi^2$ are discarded. Second, the $r^2$ veto (Rodríguez 2007), which looks at the time the $\chi^2$ statistic stays above a threshold, is applied.

The SNR and $\chi^2$ from a single detector are combined into an effective SNR (Abbott et al. 2007b). The effective SNRs from the two detectors are then added in quadrature to form a single quantity $\rho_{\text{eff}}$ which provides good separation between signal candidate events and background. The final list of coincident triggers are then called candidate events.

3.2. Background and Results

Gravitational-wave detectors are susceptible to many sources of environmental and intrinsic noise. These sources often result in non-Gaussian and non-stationary noise backgrounds. In the case of H1 and H2, which share the same vacuum enclosure, these backgrounds are correlated. To estimate the background in this search, an equal number of 180 s off-source segments were selected to the past and future of the GRB trigger. All of the data, including the on-source segment, were analyzed using the methods described above. Triggers arising from the on-source segment were then removed, as were triggers within bad quality segments, leading to an estimate of the number of accidental triggers per 180 s segment. A total off-source time of 56340 s was analyzed, corresponding to 313 trials of 180 s. The mean rate of coincidences was 2.4 per 180 s segment.

Figure 2 shows the expected number of coincidences above each $\rho_{\text{eff}}$ value in 180 s based on the analysis of the off-source times (Abbott et al. 2007b). No candidates were observed in the on-source time. Therefore, no plausible gravitational wave signals from compact binary coalescence were identified around the time of the GRB 070201.

3.3. Astrophysical Interpretation

The observations reported here can be used to constrain the distance to the GRB assuming it was caused by a compact binary merger. With similar considerations, one can also evaluate the probability that a compact binary progenitor at the distance of M31 was responsible for GRB 070201.

We discover these bounds by computing the likelihood of our observation, namely the probability that no signal would be observed in the on-source time, given the presence of a compact binary progenitor with various parameters. Denote the gravitational-wave signal by $h(t; m_2, D, \bar{\mu})$ where $m_2$ is the mass of the more massive object, $D$ is the physical distance to the binary, and $\bar{\mu} = \{m_1, \tilde{s}_1, \tilde{s}_2, \iota, \Phi_0, t_0\}$ is the mass of the less massive object, the spins, the inclination, the coalescence phase, and the coalescence time. The probability of interest is then

$$p[0| h(t; m_2, D)] = \int p(\bar{\mu}) p[0| h(t; m_2, D, \bar{\mu})] d\bar{\mu}$$

(3)

where the nuisance parameters $\bar{\mu}$ are integrated over some prior distribution $p(\bar{\mu})$. This integration was performed by injecting simulated signals into the data streams of both detectors according to the desired prior distribution, and evaluating the efficiency for recovering those injections as candidate events (as described in Sec. 3.1), as a function of $m_2$ and $D$. We choose uniform priors over $m_1$ ($1M_\odot < m_1 < 3M_\odot$), $\Phi_0$, and $t_0$; the priors for spin and inclination $\iota$ are discussed below.

Astrophysical black holes are expected to have substantial spin. The maximum allowed by accretion spin-up of the hole is $(a/M) = (cS/GM^2) < 0.9982$ (Thorne 1974) in units of the Kerr spin parameter ($S$ is the spin angular momentum of the black hole). More detailed simulations and recent observations provide a broad range of values (O’Shaughnessy et al. 2005) with a maximum observed spin $(a/M) > 0.98$ (McClintock et al. 2006). The maximum spin that a neutron star can have is estimated from a combination of simulations and observations of pulsar periods. Numerical simulations of rapidly spinning neutron stars give $(a/M) < 0.75$ (Cook et al. 1994); the maximal spin of the observed pulsar sample may be substantially lower than that. In our spinning simulations, we adopted a distribution in which the spin magnitudes are uniformly distributed between zero and $(a/M) = (cS/GM^2) < 0.98$ and $(a/M) = (cS/GM^2) < 0.75$ for the black holes and neutron stars respectively, while the direction of each spin is uniform over the sphere.
There is strong evidence that GRBs are beamed (see, e.g., Nakar 2007; Soderberg et al. 2006; Grupe et al. 2006, and references therein). If this is the case, the most likely direction for beaming is along the total angular momentum vector of the system. For binaries with small component spins, this will correspond to the direction orthogonal to the plane of the orbit. Hence the inclination angle of the binary, relative to the line of sight, is most likely to be close to zero. However, since zero inclination is the best case for detection of gravitational waves, a uniform prior on \( \cos \iota \) provides a conservative constraint. We drew \( \cos \iota \) from a uniform prior.

Figure 3 shows the contours of constant probability \( 1 - p[0 \mid h(t; m_2, D)] \). Compact binaries corresponding to \( (m_2, D) \) in the darkest-shaded region are excluded as progenitors for this event at the 90\% confidence level. As a reference point, a compact binary progenitor with masses \( 1 M_\odot < m_1 < 3 M_\odot \) and \( 1 M_\odot < m_2 < 4 M_\odot \) with \( D < 3.5 \) Mpc is excluded at 90\% confidence; the same system with \( D < 8.8 \) Mpc is excluded at the 50\% level. This result is averaged over different theoretical waveform families; 20\% of the simulated waveforms include spins sampled as described above.

A number of systematic uncertainties enter into this analysis, but amplitude calibration error (=10\%) and Monte-Carlo statistics have the largest effects. These uncertainties have been folded into our analysis in a manner similar to that described in (Abbott et al. 2005b, d). In particular, the amplitude calibration was taken into account by scaling the distance of the injection signal to be \( 1.28 \sqrt{p(1-p)/n} = p[0 \mid h(t; m_2, D)] \) where \( n \) is the total number of simulated signals in a particular mass-distance bin.

We evaluate the hypothesis that the event occurred in M31, as electromagnetic observations hint might be the case, given our observation. We adopt a the measured distance 0.77 Mpc to M31. We then simulated a large number of inspirals at distances 0.77 Mpc < \( D < 0.9 \) Mpc which allows us to account for both uncertainty in distance to M31 (7\%) (Freedman et al. 2001) and the amplitude calibration uncertainty discussed above. The simulations exclude any compact binary progenitor in our simulation space at the distance of M31 at the > 99\% level. In particular, a compact binary progenitor with masses \( 1 M_\odot < m_1 < 3 M_\odot \) and \( 7 M_\odot < m_2 < 10 M_\odot \) located in M31 would be excluded at the > 99\% level.

4. SEARCH FOR A GRAVITATIONAL WAVE BURST

To search for a gravitational wave burst associated with GRB 070201 we have used LIGO’s current baseline method for near-real time searches for gravitational wave bursts associated with GRB triggers (IPN3 2007; GCN 2007). A detailed description of the analysis method is presented elsewhere (Abbott et al. 2007a).

4.1. Search Method

The burst search method is based on cross-correlating a pair of pre-conditioned datastreams from two different gravitational wave detectors. The pre-conditioning of the datastreams consists of whitening, phase-calibration, and band-passing from 40 Hz to 2000 Hz. The cross-correlation is calculated for short time series of equal length taken from the datastreams of each detector. For discretely sampled time series \( s_1 \) and \( s_2 \), each containing \( n \) elements, the cross-correlation, \( cc \), is defined as:

\[
cc = \frac{\sum_{j=1}^{n} [s_1(j) - \mu_1][s_2(j) - \mu_2]}{\sqrt{\sum_{j=1}^{n} [s_1(j) - \mu_1]^2 \sum_{k=1}^{n} [s_2(k) - \mu_2]^2}}
\]

where \( \mu_1 \) and \( \mu_2 \) are the corresponding means of \( s_1 \) and \( s_2 \). Possible values of this normalized cross-correlation range from -1 to +1, the minus sign corresponding to anti-correlation and the plus sign to correlation.

The measurement of the cross-correlation statistic proceeded as follows. Both 180 second on-source time series of H1 and H2 data were divided into time intervals (or cross-correlation windows) of length \( T_{ccw} \) seconds. Previous analyses have shown that using two windows, \( T_{ccw} = 25 \) ms and \( T_{ccw} = 100 \) ms, is sufficient to target short-duration signals lasting from \( \sim 1 \) ms to \( \sim 100 \) ms. The intervals were overlapped by half (i.e., \( T_{ccw}/2 \)) to avoid missing a signal occurring near a boundary. The cross-correlation value, \( cc \), was calculated for each H1-H2 interval pair and for both \( T_{ccw} \) cross-correlation window lengths. The largest \( cc \) is the strength measure of the most significant correlated candidate value within the 180 second long on-source segment. To estimate the significance of this loudest event, we use off-source data to measure the cross-correlation distribution of the background noise.

4.2. Background Estimation and Search Results

Approximately 3 hours of data symmetrically distributed about the on-source segment were used to study the background. These off-source data were collected from sufficiently close to the on-source time to accurately reflect the statistical properties of the data within the on-source region. The interferometers were collecting data continuously during the off- and on-source periods. The off-source data were divided into 180 second long segments, which also correspond to the length of the on-source segment. The off-source segments were treated identically to the on-source segment.
The LSC

4.1 Gravitational-Wave Transients Associated with GRB 070201

Gravitational-Wave Transients Associated with GRB 070201

Since the analysis of the previous section showed no evidence for a gravitational wave burst, we set upper limits on the amplitude and energy of gravitational waves incident on the detectors during GRB 070201. Denote the gravitational wave signal by \( h(t; h_{\text{rss}}) \), where

\[
h_{\text{rss}} = \sqrt{\int_{-\infty}^{\infty} \left( |h_x(t)|^2 + |h_\times(t)|^2 \right) dt}
\]

is the root-sum-squared amplitude of the gravitational wave signal. To determine an upper limit, one needs the probability of measuring \( cc \) given the presence of a signal with \( h_{\text{rss}} \):

\[
p(\text{cc}|h(t; h_{\text{rss}}))
\]

The search targets signals with duration \( \lesssim 100 \text{ ms} \). Within this class of signals, the sensitivity of the search has weak dependence on signal morphology; it depends primarily on the energy and the frequency content of the signal. Therefore, as long as the frequency and duration of the injected test waveforms match the theoretical predictions, we can work with the waveform of our choice. A class of waveforms called sine-Gaussians have become the standard benchmark for burst searches and were used to construct the probability distribution given in Eq. (6). The explicit formulae for \( h_x(t) \) and \( h_\times(t) \) are

\[
h_x(t) = h_0 \sin(2\pi f_0(t-t_0)) \exp \left[ \frac{-(2\pi f_0(t-t_0))^2}{2Q^2} \right],
\]

\[
h_\times(t) = h_0 \cos(2\pi f_0(t-t_0)) \exp \left[ \frac{-(2\pi f_0(t-t_0))^2}{2Q^2} \right],
\]

where \( f_0 \) is the central frequency, \( h_0 \) is the peak amplitude of each polarization, \( t_0 \) is the peak time, and \( Q \) is a dimensionless constant which represents roughly the number of cycles with which the waveform oscillates with more than half of the peak amplitude. Since the \( h_x(t) \) and \( h_\times(t) \) waveforms have the same amplitude, these simulated gravitational wave bursts are circularly polarized.

We provide results for the characteristic case of \( Q = 8.9 \), as the dependence of the upper limits on \( Q \) is very weak. The measurement is carried out as follows. First, we choose a central frequency, \( f_0 \), and an \( h_{\text{rss}} \) value for the injected signal. From these parameters, we calculate \( h(t) \) using Eq. (1), Eq. (5), Eq. (7) and Eq. (8). We then add the calibrated \( h(t) \) to the on-source H1 and H2 data, choosing a random starting time within the segments. We then measure the largest value of cross-correlation, \( cc \), generally following the same method described in Sec. 4.1, except that in this case only a shorter interval around the injection is searched. Using the same \( h_{\text{rss}} \) values, we keep iterating the last two steps of the algorithm (randomizing a starting point and calculating the \( cc \) local maximum) until we have enough datapoints to determine the conditional probability \( p(\text{cc}|h_{\text{rss}}) \). This probability, determined for different \( h_{\text{rss}} \) values and central frequencies, is then used to set a frequentist upper limit on \( h_{\text{rss}} \), given the largest cross-correlation found for the on-source segment in the search (see Sec. 4.1) (Abbott et al. 2007a).

The resulting 90% \( h_{\text{rss}} \) upper limits are given in Table 1 for circularly polarized sine-gaussians with different central frequencies and with \( Q = 8.9 \). The frequency dependence of the upper limits follows the shape of the detector’s frequency dependent sensitivity curve.
The h_{rss} limits given in Table 1 include the calibration and statistical errors. These errors were propagated into the 90% h_{rss} upper limits using the same procedure used in (Abbott et al. 2007a). The 1σ errors considered were: (a.) calibration response phase error (100); (b.) calibration response amplitude error (10%); and (c.) statistical error determined through Monte-Carlo simulations (2.1%).

The upper limits on h_{rss} implied by the burst search can be translated into conventional astrophysical units of energy emitted in gravitational waves. The gravitational wave energy E_{GW} radiated by an \textit{isotropically emitting} source which is dominated by emission at a frequency f_{0}, is related to the h_{rss} received at distance D, much less than the Hubble distance, by (Riles 2004)

\[
E_{GW}^{iso} \approx \frac{\pi^2 c^3}{G} D^2 f_{0}^2 h_{rss}^2.
\]

Based on the sensitivity of this burst search as summarized in Table 1, we estimate that a gravitational wave burst with characteristic frequency in the most sensitive frequency region of the LIGO detectors (f \approx 150Hz), if GRB 070201 originated in M31 (at 770 kpc), must have emitted less than approximately \(4.4 \times 10^{-4}M_{\odot}c^2\) (7.9 \(10^{59}\) ergs) within any 100 ms interval in the on-source window in gravitational waves. In terms of the SGR progenitor hypothesis, our experimental upper limit on E_{GW} is several orders of magnitude larger than the 10^{45}\text{erg}(D/770\text{kpc})^{2} known to be emitted electromagnetically. And while present models for SGR bursts may differ substantially in their mechanism (de Freitas Pacheco 1998; Joka 2001a,b; Horvath 2005), they suggest that no more than 10^{46}\text{erg} is released in the form of gravitational waves. Therefore, the upper limit achievable with the present detectors does not exclude these models of SGRs at the M31 distance.

We also estimate the sensitivity of the (100 ms) burst search to gravitational waves from a compact binary progenitor in M31 (see Figure 5). We choose as examples a 1.4\text{M}_{\odot} + 1.4\text{M}_{\odot} binary and a 1.4\text{M}_{\odot} + 10\text{M}_{\odot} binary. For each mass pair, we inject approximately 1000 inspiral waveforms consistent with the distance of M31, with random isotropically distributed inclination and polarization, and with coalescence time uniformly distributed through the on-source segment. Since, for these masses, the merger phase is expected to occur at frequencies well above that of maximum LIGO sensitivity, we inject only the inspiral portion. As for the sine-Gaussian simulations, we determine the largest cross-correlation within a small time window around the coalescence time. We also account for possible systematic errors due to the calibration and the uncertainty in the distance to a possible source within M31, and statistical errors from the Monte Carlo procedure. We estimate with 90% confidence that a 1.4\text{M}_{\odot} - 1.4\text{M}_{\odot} binary inspiral in M31 at the time of GRB 070201 would have a probability of at least 0.878 of producing a cross-correlation larger than the loudest on-source event. For 1.4\text{M}_{\odot} - 10\text{M}_{\odot} binaries this probability is at least 0.989. This gives us an independent way to reject the hypothesis of a compact binary progenitor in M31, while not relying on the detailed model of the inspiral signal.

5. DISCUSSION

We analyzed the data from the LIGO H1 and H2 gravitational-wave detectors, looking for signals associated with the electromagnetic event GRB 070201. No plausible gravitational-wave signals were identified. Based on this search, a compact binary progenitor (neutron star + black hole or neutron star systems) of GRB 070201, with masses in the range \(1\text{M}_{\odot} < m_1 < 3\text{M}_{\odot}\) and \(1\text{M}_{\odot} < m_2 < 40\text{M}_{\odot}\), located in M31 is excluded at the > 99% confidence.

Our model-independent search did not find correlated signatures inconsistent with the noise within the H1 and H2 datastreams that could be related to GRB 070201. Based on the sensitivity of our search and assuming isotropic gravitational-
wave emission of the progenitor, an upper limit on the power emitted in gravitational waves by GRB 070201 was determined. A gravitational wave with characteristic frequency within the most sensitive range of the LIGO detectors ($f \approx 150$ Hz) most probably emitted less than $E_{GW} < 7.9 \times 10^{50}$ ergs within any 100-ms-long time interval inside the source region if the source is in M31. This limit on radiated power is comparable to the emitted power of some GRBs. However, it is significantly higher than the associated electromagnetic emission of this particular GRB. Therefore the transient search only constrains the binary inspiral models for a short hard GRB in M31 and does not impose new limitations on magnetar-driven (SGR type) burst models.

As gravitational-wave observations continue and the sensitivity of the instruments improves, we look forward to the astrophysical insights that combined electromagnetic and gravitational observing campaigns can bring.

We are indebted to the observers of the electromagnetic event, the GCN and the IPN networks for providing us with valuable data and real time information.

The authors gratefully acknowledge the support of the United States National Science Foundation for the construction and operation of the LIGO Laboratory and the Science and Technology Facilities Council of the United Kingdom, the Max-Planck-Society, and the State of Niedersachsen/Germany for support of the construction and operation of the GEO-600 detector. The authors also gratefully acknowledge the support of the research by these agencies and by the Australian Research Council, the Council of Scientific and Industrial Research of India, the Istituto Nazionale di Fisica Nucleare of Italy, the Spanish Ministerio de Educación y Ciencia, the Conselleria d’Economia, Hisenda i Innovació of the Govern de les Illes Balears, the Scottish Funding Council, the Scottish Universities Physics Alliance, The National Aeronautics and Space Administration, the Carnegie Trust, the Leverhulme Trust, the David and Lucile Packard Foundation, the Research Corporation, and the Alfred P. Sloan Foundation.

We are grateful to the GALEX collaboration for providing the UV image of M31, the SDSS project for providing the optical image of M31 and Google Sky to accelerate the error box position verification.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Mombukagakusho, the Max Planck Society, and the Higher Education Funding Council for England. The SDSS Web Site is http://www.sdss.org/.

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, University of Cambridge, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.

This paper was assigned a LIGO Document Number: LIGO-P070081-04-Z.
